From a purely statistical perspective, spatial data is multivariate data with special covariates: the coordinates.

Tobler's first law of Geography states [10]:

Everything is related to everything else, but near things are more related than distant things.

Coordinate Reference System

We model the earth, but think in maps: locations are projected from a curved surface in 3D to flat 2D space.

Be aware of geographic coordinates and different projections that maintain angles, certain distances or area.

Imagine the following distances between:

- the Fjord of Oslo (59.85 N 10.75 E) and Uppsala (59.85 N 17.63 E) that are at the same latitude:

To distinguish different projections, a well prepared data set comes with its coordinate reference system (CRS) as metadata.

These are often encoded as

- EPSG-codes (by the European Petroleum Survey Group)
- proj4string

They define how the reference surface (sphere, ellipsoid) is fixed to the real world (called the datum) and how the projection (surface in 3D to 2D plane) is made.

Point Patterns

Records of locations of events are referred to as *Point Patterns* (e.g. locations of earthquakes).

Adding an attribute (e.g. magnitude) to the raw locations generates a *marked point pattern*.

Lattice

Data collected per region is referred to as *lattice* data (e.g. number of birth per county).

These values are true per region, but generally not observable at each point in that region.

Fields

Fields are understood as continuously spreading over space (e.g. temperature recordings) and typically observed at a set of distinct locations and illustrated as interpolated maps. Typically, fields are modelled as a realisation of a spatial random field.

Following the algorithm by [4], we seek a model where the intensity λ is log-linear in the parameter θ :

$$\log(\lambda_{\theta}(x, y)) = \theta \cdot f(x, y)$$

A model fit with f being a simple linear model of the coordinates, is obtained through

```
> modelL1 <- ppm(longleaf, ~x+y)
> modelL1
Nonstationary Poisson process
```

```
Trend formula: ~x + y
> AIC(modelL1)
6077

The motivation of a *conditional autoregressive model* is given by the conditional distribution

$$f(z(s_i) | \{z(s_j) : j \neq i\}) \\ = \frac{1}{\tau_i \sqrt{2\pi}} \exp \left(\frac{-(z(s_i) - \theta_i(\{z(s_j) : j \neq i\}))^2}{2\tau_i^2} \right)$$

with

$$\theta_i(\{z(s_j) : j \neq i\}) = \mu_i + \sum_{j=1}^n c_{ij} (z(s_j) - \mu_j)$$

while $(c_{ij})_{ij}$ with $c_{ij} = 0$ unless the locations s_i and s_j are pairwise dependent, $c_{ij}\tau_i^2 = c_{ji}\tau_j^2$ and $c_{ii} = 0$. τ_i^2 .

The process Z can then be modelled as

$$Z \sim \text{Gau}(\boldsymbol{\mu}, (\mathbf{I} - \mathbf{C})^{-1}\mathbf{M})$$

$$Z(s_i) = \mu_i + \sum_{j=1}^n c_{ij}(Z(s_j) - \mu_j) + \nu_i$$

with $\boldsymbol{\nu} \sim \text{Gau}(\mathbf{0}, \mathbf{M}(\mathbf{I} - \mathbf{C}^t))$ while $\mathbf{M} = \text{diag}(\tau_1^2, \dots, \tau_n^2)$,
 $\mathbf{C} = (c_{ij})_{ij}$.

Typically, only a small number of conditioning sites is used
assuming the Markov property

$$f(z(s_i) | \{z(s_j) : j \neq i\}) = f(z(s_i) | \{z(s_j) : j \in N_i\})$$

with N_i being the index set of selected neighbouring
locations.

A *simultaneous autoregressive model* is given by

$$Z \sim \text{Gau}(\boldsymbol{\mu}, (\mathbf{I} - \mathbf{B})^{-1} \Lambda (\mathbf{I} - \mathbf{B}^t)^{-1})$$

$$Z(s_i) = \mu_i + \sum_{j=1}^n b_{ij} (Z(s_j) - \mu_j) + \epsilon_i$$

with $\epsilon \sim \text{Gau}(\mathbf{0}, \Lambda)$, $B = (b_{ij})_{ij}$ while $b_{ii} = 0$ and b_{ij} captures the dependence of location s_i on s_j . It is not necessarily $b_{ij} = b_{ji}$, but $(\mathbf{I} - \mathbf{B})^{-1}$ is assumed to exist.

stationarity The process "looks" the same at each location (e.g. mean and variance do not change from east to west)

isotropy The dependence between locations is determined only by their separating distance neglecting the direction (e.g. locations 2 km apart along the north-south axis are as correlated as stations 2 km apart along the east-west axis)

Some tricks exist to weaken these assumptions (e.g. rotating and rescaling coordinates).

Variograms II

The *sample variogram* is obtained through

```
vgmMeuse <- variogram(zinc~1, meuse)
```

Certain variogram models can be used to parametrize a covariance matrix for a Gaussian random field over a finite set of locations s_1, \dots, s_n :

$$Z \sim \text{Gau}(\boldsymbol{\mu}, \Sigma)$$

while $\Sigma = (\sigma_{ij}^2)_{ij}$ and $\sigma_{ij}^2 = \sigma^2 - \gamma(\|s_i - s_j\|)$, $1 \leq i, j \leq n$ with $\sigma^2 = \text{Var}(Z(s))$, $\boldsymbol{\mu} = (\mu_1, \dots, \mu_n)$.

Predictions can be made using matrix inversion and matrix multiplications.

$S \times T$ works as a data structure, but modelling needs to consider special properties of the product of space and time.

direction Today's values influence tomorrow, but will not take effect on yesterday's values.

anisotropy What is the equivalent in terms of dependence of 1 m separation in seconds or minutes?

The easiest way to think of spatio-temporal data is as time slices - but this neglects the temporal dependence.

After modelling temporal trend or periodicities, the residuals might be modelled as a spatio-temporal random field.

Extending the variogram to a twoplace function for spatio-temporal random fields $Z(s, t)$:

$$\gamma(h, u) = E(Z(s, t) - Z(s + h, t + u))^2$$

at any location (s, t) . And empirical version

$$\hat{\gamma}(h, u) = \frac{1}{2|N_{h,u}|} \sum_{(i,j) \in N_{h,u}} (Z(s_i, t_i) - Z(s_j, t_j))^2$$

$$\text{while } N_{h,u} = \left\{ (i, j) \left| \begin{array}{l} h - \epsilon_s \leq \|s_i - s_j\| \leq h + \epsilon_s \\ u - \epsilon_t \leq t_i - t_j \leq u + \epsilon_t \end{array} \right. \right\}$$

Modelling dependence over space differently from the dependence over time yields another degree of freedom.

metric the temporal component is adjusted using only an anisotropy correction

$$\gamma_m(h, u) = \gamma_j(\sqrt{h^2 + (\kappa \cdot u)^2})$$

separable spatial and temporal component are added up neglecting interactions between space and time

$$\begin{aligned}\gamma_{sep}(h, u) &= \text{nug} \cdot \mathbf{1}_{h>0, u>0} \\ &+ \text{sill} \cdot (\gamma_s(h) + \gamma_t(u) - \gamma_s(h)\gamma_t(u))\end{aligned}$$

product-sum a product interaction term is added to the separable model

$$\begin{aligned}\gamma_{ps}(h, u) &= \text{nug} \cdot \mathbf{1}_{h>0, u>0} \\ &+ \gamma_s(h) + \gamma_t(u) - k\gamma_s(h)\gamma_t(u)\end{aligned}$$

The parameter k needs to fulfil
 $0 < k \leq 1/(\max(\text{sill}_s, \text{sill}_t))$.

sum-metric the covariance structure is composed out of spatial and temporal components added with a metric model capturing interactions

$$\gamma_{sm}(h, u) = \gamma_s(h) + \gamma_t(u) + \gamma_j(\sqrt{h^2 + (\kappa \cdot u)^2})$$

Copulas allow to model dependencies much more detailed than a typical correlation value.

Instead of a single value, a full distribution is fitted describing dependence.

The power of copulas originates from Sklar's Theorem [9]:

Any multivariate distribution H can be decomposed into its marginal distribution functions F_1, \dots, F_d and its copula C :

$$H(x_1, \dots, x_d) = C(F_1(x_1), \dots, F_d(x_d))$$
